Abstract

I consider the quantum electromagnetic field in a coaxial cylindrical waveguide, such that the outer cylindrical surface has a time-dependent radius. The field propagates parallel to the axis, inside the annular region between the two cylindrical surfaces. When the mechanical frequency and the thickness of the annular region are small enough, only Transverse Electromagnetic (TEM) photons may be generated by the dynamical Casimir effect. The photon emission rate is calculated in this regime, and compared with the case of parallel plates in the limit of very short distances between the two cylindrical surfaces. The proximity force approximation holds for the transition matrix elements in this limit, but the emission rate scales quadratically with the mechanical frequency, as opposed to the cubic dependence for parallel plates.

The reflection of vacuum fluctuations by an oscillating mirror generates frequency sidebands. This frequency modulation mixes up positive and negative field frequencies below the mechanical frequency. Because of the association between positive (negative) frequencies and annihilation (creation) operators, this mixing leads to the creation of real low-frequency photon pairs out of the vacuum field state. The very small orders of magnitude involved in this “dynamical Casimir” effect have so far ruled out its experimental verification. For a single plate moving in vacuum, the photon emission rate is of the order of a few microwave photons per day even for mechanical frequencies as high as 10 GHz [1].

Much higher orders of magnitude are obtained if the mechanical frequency is tuned into parametric resonance with a microwave high- Q closed cavity [2]. Another possibility is to consider the dynamical counterpart of the original configuration proposed by Casimir [3], with two parallel plates moving along the direction perpendicular to the plates (z direction) [4]. Assume that one of the plates oscillates with frequency ω_0 : $\delta z_1(t) = \delta z_0 \cos \omega_0 t$, and the second plate is at rest at $z_2 = a$. Since this ‘cavity’ is laterally open, the spectrum of field modes is continuous, and there is no re-cycling of photons (except in the very particular case of propagation along the z direction). As a consequence, one may employ a perturbative

approach, which is implemented either by considering the frequency sidebands discussed above, or alternatively by using standard Hamiltonian perturbation theory. Since there is a continuous of final states, from Fermi golden rule the average photon number is proportional to time, allowing one to define the photon production rate as the physical quantity of interest.

For short values of the average distance a , $\omega_0 a / (\pi c) < 1$, the photon production rate is given by [4]

$$\frac{dN}{dt} = \frac{1}{64} \frac{A \omega_0^3 \delta z_0^2}{c^2 a^2}, \quad (1)$$

where A is the area of the plates. As compared to the single-plate configuration, the emission rate is enhanced by the factor $1/(\omega_0 a / c)^2$ for short distances. If we take $\omega_0 / (2\pi) = 10\text{GHz}$, $v_0 = \omega_0 \delta z_0 = 10^{-7}c$, and $A \omega_0^2 / c^2 = (2\pi)^2 [A = (3\text{cm})^2]$ we find

$$\frac{dN}{dt} = 8.8 \times 10^3 \text{sec}^{-1} \quad (2)$$

for $a = 1\mu\text{m}$. In this regime, all photons have frequency $\omega_0/2$, and Transverse Magnetic (TM) polarization (magnetic field perpendicular to the z axis). The electric field is parallel to the z axis and constant along this direction. In waveguide language, this corresponds to TEM polarization, since both electric and magnetic fields are perpendicular to the direction of propagation, which is parallel to the xy plane. The ‘twin’ photons in a given pair propagate along opposite directions, and the total production rate is uniformly distributed over the 2π angle in the xy plane. In this sense, the parallel-plates configuration is not an efficient waveguide, because all directions in the xy plane are equivalent by symmetry.

In this paper, I consider the dynamical Casimir effect in a coaxial cylindrical waveguide. As compared with the parallel-plates setup, it has the advantage of concentrating the emission rate over the two opposite directions along the z axis. The inner cylinder has radius b , whereas the outer cylindrical surface has a time-dependent radius $b + a + \delta\rho(t)$, with

$$\delta\rho(t) = \delta\rho_0 \cos \omega_0 t. \quad (3)$$

The field propagates in the annular region of thickness $a + \delta\rho(t)$ between the two perfectly-reflecting cylindrical surfaces.

We assume that ω_0 is below the frequency cutoff for propagation of TE and TM waveguide modes. Since the emitted photons have frequencies below ω_0 , they necessarily correspond to TEM modes. Thus, from now on we only analyze these modes. We take periodic boundary conditions over the axial length L , which is to be identified with the (very long) length of the waveguide. Then, the electric field is given by the Fourier series

$$\mathbf{E}^{\text{TEM}}(\rho, \phi, z, t) = \sum_{n=-\infty}^{\infty} \mathbf{E}_n^{\text{TEM}}(\rho, \phi, t) \exp(in\pi z/L)$$

with

$$\mathbf{E}_n^{\text{TEM}}(\rho, \phi, t) = i \sqrt{\frac{\hbar \omega_n}{4\pi \epsilon_0 L \log(1 + a/b)}} \frac{a_n e^{-i\omega_n t} \hat{\rho}}{\rho} + \text{H.c.}, \quad (4)$$

$[a_n, a_{n'}^\dagger] = \delta_{n,n'}$, and $\omega_n = |n|\pi c/L$. The magnetic field is given by $\mathbf{B}_n^{\text{TEM}} = \text{sgn}(n)\hat{z} \times \mathbf{E}_n^{\text{TEM}}/c$.

The effect of the motion is modeled by the perturbation Hamiltonian representing the negative of the work done on the expanding/contracting cylindrical surface:

$$\delta V(t) = -(a+b) \int_0^{2\pi} d\phi \int_0^L dz \lim_{\epsilon \rightarrow 0^+} T_{\rho\rho}(a+b-\epsilon, \phi, z) \delta\rho(t), \quad (5)$$

where

$$T_{\rho\rho} = \frac{\epsilon_0}{2} (E_\rho^2 - B_\phi^2) \quad (6)$$

is the suitable component of the Maxwell stress tensor. Being quadratic in the bosonic field operators, it leads to the generation of photon pairs within first-order time-dependent perturbation theory. We assume the field to be initially in the vacuum state, $|\psi\rangle_0 = |0\rangle$, and write the field state at time Δt as

$$|\psi\rangle_{\Delta t} = b(\Delta t)|0\rangle + \sum_{\{n_1, n_2\}} c_{\{n_1 n_2\}}(\Delta t) |\{n_1^{\text{TEM}}; n_2^{\text{TEM}}\}\rangle, \quad (7)$$

where the sum is over all pairs of integers $\{n_1, n_2\}$ regardless of the ordering, so that each two-photon state appears only once in (7). The two-photon amplitudes are calculated with the help of first-order perturbation theory:

$$c_{\{n_1 n_2\}}(\Delta t) = -\frac{i}{\hbar} \int_0^{\Delta t} \langle \{n_1^{\text{TEM}}; n_2^{\text{TEM}}\} | \delta V(t') | 0 \rangle \exp[i(\omega_{n_1} + \omega_{n_2})t'] dt'. \quad (8)$$

The matrix elements appearing in (8) are computed from (4) and (6) after replacing the integral over z in (5) by a sum over Fourier components. The electric and magnetic contributions are equal, yielding

$$\langle \{n_1^{\text{TEM}}; n_2^{\text{TEM}}\} | \delta V(t) | 0 \rangle = \frac{\hbar \omega_{n_1} \delta\rho(t)}{(a+b) \log(1+a/b)} \delta_{n_1, -n_2}. \quad (9)$$

At this point, it is illustrative to compare this result with the case of two parallel plates discussed in the beginning. The matrix elements of the field operator representing the force on the left-hand plate are given by Eq. (47) of Ref. [4] (correcting a misprint):

$$\langle \{\mathbf{n}_1 \ell_1^{\text{TM}}, \mathbf{n}_2 \ell_2^{\text{TM}}\} | F | 0 \rangle = \frac{\hbar}{a} \frac{c^2 (k_{\parallel}^{n_1})^2 + \omega_{n_1}^{\ell_1} \omega_{n_1}^{\ell_2}}{\sqrt{(1 + \delta_{\ell_1 0})(1 + \delta_{\ell_2 0})} \omega_{n_1}^{\ell_1} \omega_{n_1}^{\ell_2}} \delta_{\mathbf{n}_1, -\mathbf{n}_2}. \quad (10)$$

The TM-polarized two-photon states in Eq. (10) are characterized by two sets of integer numbers n_x, n_y and ℓ , where $\mathbf{n} = n_x \hat{x} + n_y \hat{y}$ defines the component of the wavevector parallel to the plates: $\mathbf{k}_{\parallel}^{\mathbf{n}} = \mathbf{n}\pi c/\sqrt{A}$; and ℓ defines the wavelength of the standing wave along the z direction.

The corresponding frequency is given by $\omega_n^\ell = c\sqrt{(k_{\parallel}^n)^2 + (\ell\pi/a)^2}$.

As discussed above, at low mechanical frequencies and short distances, only TM modes with $\ell = 0$ are excited. The corresponding matrix elements of the perturbation Hamiltonian $\delta V(t) = -F\delta z_1(t)$ are obtained from Eq. (10) and written in terms of the displacement $\delta\rho = -\delta z_1$ representing an increase of the separation as in the problem of the coaxial waveguide:

$$\langle \{n_1 0_{\text{TM}}; n_2 0_{\text{TM}}\} | \delta V(t) | 0 \rangle = \frac{\hbar\omega_{n_1}^0 \delta\rho(t)}{a} \delta_{n_1, -n_2}. \quad (11)$$

This coincides with the result for the matrix elements in the cylindrical waveguide as given by (9) in the limit $a \ll b$. Thus, a variant of the proximity force approximation applies for the transition matrix elements of the force/stress tensor operators, allowing for a direct comparison between the coaxial waveguide and parallel plates configurations.

On the other hand, the emission rates themselves are very different, because for the parallel plates there are two unconstrained spatial dimensions, and only one for the cylindrical waveguide. The emission rate in this second configuration is derived from the combination of the matrix elements given by (9) with the one-dimensional free-space density of modes, rather than the two-dimensional density for the parallel plates. When replacing (3) into (9), we neglect the counter-rotating term and derive the probability of pair creation from (8):

$$|c_{\{n_1 n_2\}}(\Delta t)|^2 = \left(\frac{\omega_{n_1} \delta\rho_0}{(a+b) \log(1+a/b)} \right)^2 \frac{\sin^2(\Delta\omega \Delta t/2)}{\Delta\omega^2} \delta_{n_1, -n_2}, \quad (12)$$

with

$$\Delta\omega = \omega_{n_1} + \omega_{n_2} - \omega_0 = 2\omega_{n_1} - \omega_0.$$

The average photon number at time Δt is given by

$$\Delta N = \sum_n |c_{n, -n}(\Delta t)|^2. \quad (13)$$

Then we replace $\sum_n \rightarrow L \int dk / (2\pi)$, and calculate the resulting integral in the limit $\Delta t \rightarrow \infty$, so that the function $\sin^2(\Delta\omega \Delta t/2)/\Delta\omega^2$ is sharply peaked around $\omega_n = \omega_0/2$. Hence the twin photons of a given pair share the same frequency $\omega_0/2$, and propagate along opposite directions along the z axis because $n_1 = -n_2$ in Eqs. (9) and (12). The resulting ΔN is proportional to Δt , allowing for the definition of the emission rate $dN/dt = \Delta N/\Delta t$, with

$$\frac{dN}{dt} = \frac{1}{16} \frac{L\omega_0^2 \delta\rho_0^2}{c(a+b)^2 [\log(1+a/b)]^2} \quad (14)$$

The emission rate is maximized for $b \gg a$, yielding

$$\frac{dN}{dt} = \frac{1}{16} \frac{L\omega_0^2 \delta\rho_0^2}{c a^2}. \quad (15)$$

By following the same method, one derives the emission rate for parallel plates, as given by Eq. (1), from the common value for the matrix element given by Eq. (11), thus resulting in $1/a^2$

dependence for both configurations [5]. From this point, the different powers of ω_0 in Eq. (1) and Eq. (15) may be inferred by dimensional analysis, after taking into account the necessary factors of length and area for the two setups.

When taking the same parameters discussed in connection with Eq. (2), and with $L\omega_0/c = 2\pi$ [$L = 3\text{cm}$], we find

$$\frac{dN}{dt} = 5.6 \times 10^3 \text{ sec}^{-1}. \quad (16)$$

As for Eq. (2), this is only an estimate of the order of magnitude, since this value of L is of the order of the typical wavelengths. In fact, diffraction at the borders of the waveguide, not taken into account here, are negligible only if $L\omega_0/(2\pi c) \gg 1$, corresponding to unrealistic values of L .

In summary, the emission rate for a long cylindrical waveguide was computed from Hamiltonian first-order perturbation theory. This rate is slightly smaller than the value for parallel plates. However, all photons propagate along the axis of the waveguide, whereas for the parallel plates the total emission rate is divided between all directions parallel to the plates. In spite of the lower orders of magnitude, the dynamical Casimir effect in waveguides has some advantages when compared with the closed cavity setups. There is no need to tune the mechanical frequency ω_0 into parametric resonance with the very sharp cavity resonances, and the emission rate is a simple power law function of ω_0 . The generated photons are not confined in a high-Q cavity, and hence are more easily available for detection. Finally, the twin photons in a given pair are created simultaneously, opening (a somewhat remote) way for coincidence measurements [6].

- [5] In Ref. [4], the average photon number was computed for the following motion: $\delta z_1 = \delta z_0 \exp(-|t|/\Delta t) \cos(\omega_0 t)$, and then the rate was derived by dividing it by Δt . The result agrees with the present derivation because the integrated squared amplitude is $\int \delta z_0^2 \exp(-2|t|/\Delta t) dt = \delta z_0^2 \Delta t$. Hence the integrated effect of the motion from $-\infty$ to ∞ turns out to be equivalent to the effect of a constant amplitude from $t = 0$ to $t = \Delta t$.

- [6] In a closed cavity, the leakage of the intracavity photons (and more generally any loss mechanism) is a random process that destroys the time correlation between the twin photons.
